### Abstract

Pemphigus vulgaris is a life threatening chronic autoimmune disease characterized by the formation of intraepithelial blisters on the skin and mucous membranes. Pemphigus vulgaris initially manifests in the form of intraoral lesions which spread to other mucous membranes and the skin. Pemphigus vulgaris (PV), the most common and important variant, is an autoimmune blistering disease characterized by circulating pathogenic IgG (immunoglobulin) antibodies against desmoglein 3 (Dsg3), about half the patients also having Dsg1 autoantibodies. Oral lesions are initially vesiculobullous but readily rupture, new bullae developing as the older ones rupture and ulcerate.

Biopsy of perilesional tissue, with histological and immunostaining examinations, is essential to the diagnosis. The diagnosis is based on clinical findings and laboratory analyses, and it is usually treated by the combined administration of corticosteroids and immunosuppressants. Detection of the oral lesions can result in an earlier diagnosis. The current review focuses on the etiopathogenesis, diagnosis and current treatment of pemphigus vulgaris.

**Keywords** Pemphigus; Oral mucosa; Autoimmune bullous disease.

### Introduction

Pemphigus vulgaris (PV) is a chronic autoimmune mucocutaneous diseases characterized by the formation of intraepithelial blisters. It is a rare disease (0.1-0.5 cases/100,000 inhabitants/yr), with onset usually in the fifth or sixth decade of life.<sup>(1)</sup>

Various research have considered pemphigus as idiopathic in nature but strong evidences suggest it to be a disorder which is autoimmune in nature and is due to the presence of production of antibodies

PV results from an autoimmune process in which autoantibodies are produced against the desmoglein protein which his adhesive protein and is responsible for holding the cells of epithelium together.<sup>(2)</sup>

Dsg 3 is mainly present in the oral cavity while the desmoglein 1 is present over the skin region. The serum antibodies responsible for PV are always IgG type and these antibodies act against the desmoglein adhesion protein and lead to formation of bulla.<sup>(1)</sup> (Table 1)

The diagnosis of PV is based on three independent set of criteria: clinical features, histology, and immunological tests.<sup>(3)</sup>

Research advances have expanded the therapeutic arsenal against PV, which now includes treatments with: pulse therapy (intravenous infusion of very high doses of immunosuppressants for a short time period); high doses of intravenous immunoglobulin; plasmapheresis; immunospecific immunoadsorption; extracorporeal photopheresis with exposure of serum to psoralens and UVA; antagonists of tumor necrosis factor a (TNFa); cholinergic antagonists; and anti- CD20 monoclonal antibodies (e.g., rituximab).<sup>(4)</sup> However, no treatment has demonstrated superiority over the others.

*Beutner and Jordon et al (1964)* The separation of cells, called acantholysis, takes place in the lower layers

of the stratum spinosum. Whereas according to Jordan et al it was noted that Ig G autoantibodies are present in the sera which acts against the desmoglein protein which is responsible for cell to cell adhesion.

*Mahoney MG (1998)* said that the underlying mechanism responsible for causing the intraepithelial lesion of PV is the binding of IgG autoantibodies to desmoglein 3, a transmembrane glycoprotein adhesion molecule present on desmosomes. Some investigators believe that binding of the PV antibody activates proteases, whereas more recent evidence supports the theory that the PV antibodies directly block the adhesion function of the desmogleins.<sup>(6)</sup> The separation of cells, called acantholysis, takes place in the lower layers of the stratum spinosum. Immunofluorescent finding shows the earliest epithelial changes as a loss of intercellular cement substance; this is followed by a widening of intercellular spaces, destruction of desmosomes, and finally cellular degeneration with ulceration (Fig. 1, 2). In a nonimmunologic reaction, a drug directly stimulates monocytes or lymphocytes to release cytotoxic chemical mediators. No immune response is involved in this situation, and these reactions are not antibody dependent.

**Fig. 2**

### Investigation and diagnosis

*Davenport S et al (2001)* mentioned that diagnosis of pemphigus depends on biopsy confirmation of intraepithelial vesicle formation, acantholysis and the presence of Tzanck cells.<sup>(7)</sup>

*Ettlin DA et al (2005)* discussed that demonstration of immunoglobulins especially IgG and complement in the intercellular space by direct immunofluorescence (DIF) is a very reliable test for pemphigus vulgaris.<sup>(8)</sup>

*Scully C et al (2002)* said that Indirect Immunofluorescence studies enable a search for circulating auto antibodies in the patient's serum and are usually performed after direct immunofluorescence studies reveal antibody deposits in the mucosa or skin.<sup>(9)</sup>

*Bhol K et al (1998)* reported that ELISA is a quantitative method for measuring antibody levels and a useful test for the diagnosis of pemphigus. This method is more sensitive and specific than IIF. It is also superior to sophisticated immunoblotting techniques.<sup>(10)</sup>

*Davenport S et al (2001)* mentioned that diagnosis of pemphigus depends on biopsy confirmation of intraepithelial vesicle formation, acantholysis and the presence of Tzanck cells.<sup>7</sup>

*Ettlin DA et al (2005)* discussed that demonstration of immunoglobulins especially IgG and complement in the intercellular space by direct immunofluorescence (DIF) is a very reliable test for pemphigus vulgaris.<sup>(8)</sup>

*Scully C et al (2002)* said that Indirect Immunofluorescence studies enable a search for circulating auto antibodies in the patient's serum and are usually performed after direct immunofluorescence studies reveal antibody deposits in the mucosa or skin.<sup>(9)</sup>

*Bhol K et al (1998)* reported that ELISA (enzyme linked immunosorbant assay) is a quantitative method for measuring antibody levels and a useful test for the diagnosis of pemphigus. This method is more sensitive and specific than indirect immunofluorescence. It is also superior to sophisticated immunoblotting techniques.<sup>(10)</sup>

### Management of pemphigus vulgaris

*Silverman S L et al (1985)* proposed that treatment protocol for the initial/induction phase for PV typically involves the use of moderate to high dose (60 to 80 mg/day in a single morning dose) corticosteroids and an adjunctive immunosuppressive drug, azathioprine, 100 to 150 mg/day, for steroid-sparing effect, thereby

reducing steroid-induced side effects.<sup>(11)</sup> Moderate to high doses of corticosteroids administered daily, as a single dose, for 2 to 3 weeks are generally safe and well tolerated. Potential side effects of long-term steroid therapy have been extensively reviewed.

*Tan-Lim R et al (1990)* stated that Plasmapheresis is the process by which plasma is removed from blood using a cell separator as antibodies are contained within plasma, plasmapheresis results in the removal of the pathogenic PV autoantibodies.<sup>(12)</sup> Multiple case series have evaluated the efficacy of plasmapheresis in treating PV. 20-23 Of the 28 patients evaluated in these studies, 18 (64%) experienced complete remission, 6 (33%) experienced partial remission and 4 (22%) had no clinical improvement. Adverse effects encountered included systemic infections, acute hepatitis, thrombocytopenia, anemia, hypocalcemia, nausea, dizziness, urticaria, fever, and hypotension. In a multicentric study (n=40) were randomized to receive prednisolone alone or prednisolone plus large-volume plasma exchange.<sup>(12)</sup>

While plasmapheresis failed to demonstrate a therapeutic benefit in this study, it has been suggested that an additional immunosuppressive (i.e., cyclophosphamide) or immunomodulatory (i.e., IVIg) therapy may be required to prevent the rebound production of pathogenic autoantibodies associated with disease flares. High dose intravenous immunoglobulin (IVIg) has been reported to be of benefit as a steroid-sparing agent in the management of patients with PV. In a review of eight reports high dose IVIg was effective in 17 of 18 patients. Cyclophosphamide is an alkylating cytotoxic agent that is a highly effective steroid sparing agent. In a review of five studies with a total of 51 patients, complete remission was achieved in 32% of patients. The rate of remission for each of the five studies that were reviewed was very wide (0%–80%), reflecting the small number of patients in each study. Cyclophosphamide has been used as pulse therapy (1 g intravenously every four weeks).<sup>(12)</sup>

*Rook AH et al (1990)* mentioned that Extracorporeal photochemotherapy (ECP) is a new form of immunotherapy which involves the extracorporeal photoinactivation of peripheral blood cells by 8-methoxypsoralen in the presence of ultraviolet A irradiation, followed by readministration of the cells. There are only 2 small case series and 2 case reports in the literature that document the use of ECP for refractory PV. Of the 9 PV patients treated with ECP in these studies, all experienced significant clinical improvement, while no adverse effects from ECP were noted.<sup>(13)</sup>

*Shimanovich I et al (2006)* said that Immunoabsorption resulted in a dramatic clinical response and a rapid decline in desmoglein-specific IgG autoantibodies. Recently, a small case series demonstrated that IA, administered in combination with

rituximab, may result in long-term remission. In all studies, IA was safe and well tolerated.<sup>(14)</sup>

Harman KE et al (2003) concluded that systemic corticosteroids are still the most frequently used drugs and best-established therapy in pemphigus. The guidelines for management of PV by the British Association of Dermatologists recommends patients with mild disease to receive an initial prednisolone dosage of 40 to 60 mg/d and in more severe cases, 60 to 100 mg/d. If no response is achieved within 1 week, the dosage is increased by 50% to 100% until disease control.<sup>(15)</sup>

Yeh SW & Sami N (2005) reported that adjuvant drugs are usually administered in combination with systemic corticosteroids so as to reduce corticosteroid related side effects and increase efficacy. Conventional adjuvants include various immunosuppressive agents such as azathioprine, mycophenolate mofetil, methotrexate, cyclophosphamide, chlorambucil and cyclosporine, as well as anti-inflammatory agents such as gold, dapsone, colchicine and a variety of tetracycline antibiotics.<sup>(16)</sup> (Table 1)

Bystryn JC et al (2002) discussed that Intravenous Immunoglobulin (IVIg) is a fractionated and purified blood product derived from the plasma of between 1,000 and 15,000 healthy donors per batch. It contains a high concentration of IgG and has a broad range of antibodies directed against pathogens, foreign antigens, and self-antigens. Although its exact mechanism of action remains unclear, IV IgG is associated with a rapid and selective decline in the serum levels of pathogenic PV autoantibodies.<sup>(17)</sup>

Jacobi A et al (2005) stated that TNF- $\alpha$  antagonists, tumor necrosis factor may be beneficial for the treatment of PV as experimental studies have demonstrated that TNF- $\alpha$  plays a role in the acantholytic process. Two case reports document the successful use of Infliximab for refractory PV.<sup>(18)</sup>

Anhalt G et al (2005) concluded that selective therapy using Intravenous Desmoglein 3 peptides was developed to suppress the production of anti-desmoglein 3 antibodies through inactivation and/or deletion of disease-associated CD4+ T lymphocytes.<sup>(19)</sup>

Joly P & Mouquet et al (2007) mentioned that Rituximab is a chimeric murine/human IgG1 anti-CD20 monoclonal antibody that targets pre-B and mature B lymphocytes, resulting in complement and antibody-dependent cytotoxicity and apoptosis. Multiple case reports suggest that rituximab is an effective treatment option for PV.<sup>(20)</sup> The largest clinical study evaluating the use of rituximab in PV has been a case series of 14 patients with refractory PV in which 12 (86%) experienced a complete remission at 3 months after a single cycle of rituximab.

Schmidt E et al (2007) concluded that Rituximab is a chimeric murine/human IgG1 anti-CD20 monoclonal antibody that targets pre-B and mature B lymphocytes, resulting in complement and antibody-dependent cytotoxicity and apoptosis. Rituximab reduces circulating B cells, thereby preventing their maturation into antibody-producing plasma cells.<sup>(21)</sup>

Of the 18 patients with refractory PV reviewed, 3 (17%) experienced complete remission, 4 (22%) experienced clinical remission with further therapy required and 11 (61%) experienced partial remission.

**Table 1: Drug Regimes in Management of Pemphigus Vulgaris**

Drug type	Systemic Agent	Mode of Administration	Dose
Systemic corticosteroid	Prednisolone	Oral	1-2mg/kg/d
	Dexamethasone	Oral or IV Pulse	50-200/d for 3-5 day
	Methyl prednisone	IV Pulse	
Immunosuppressive and Antinflammatory Agents	Azathioprine	Oral	3-4mg/kg/day
	Chlorambucil	Oral	6-9mg/d
	Cyclophosphamide	Oral	20mg/d
	Cyclosporine	Oral	5-30mg/wk
	Dapsone	Oral	100-200mg/d
	Erythromycin	Oral	1,200 mg/day
	Gold	IM Injection	25-50mg/weekly
	Leflunomide	Oral	50-200mg/day
	Minocycline	Oral	20mg/d
	Mycophenolate	Oral	25-50 mg biweekly
Tetracyclin	Oral	30-45 mg/d	

## Conclusion

The diagnosis of PV at an early stage when it is limited to oral cavity requires careful assessment and correlation of the clinical appearance, histological features and immunofluorescence findings. Their exist various treatment modality for treating Pemphigus

which may range from topical and systemic steroid to current immunomodulators. The incidence of remissions in pemphigus is unclear, because these are usually reported at a single point in the evolution of the disease. Thus, it is uncertain whether treatment simply suppresses the manifestations of the disease and

consequently must be continuously administered, or induces complete and long-lasting remissions that permit therapy to be discontinued. The prognosis of untreated oral lesions is a progression that involves other mucosa, including the skin. When treated, the prognosis depends on the age of the patient, the initial severity, the extent of lesions, the interval between symptom onset and start of treatment, and the drug dose required to control the disease, among other factors.
